- Medium Access Control (MAC) algorithms used to control access in wireless networks
- MAC protocol preventing neighbors from transmitting simultaneously (collision and loss of packets impossible)
- Maximal stability: all nodes in the network can transmit all arriving packets for all arriving processes
- Centralized algorithms : MaxWeight/ α -fair algorithms are known to be maximally stable
 - Need a centralized controller to make decisions
- Decentralized algorithms : Carrier Sense Multiple Access (CSMA, used in IEEE 802.11)
 - Nodes have a random back-off time and transmit if they don't sense another transmission

< □ > < 同 > < 回 > < Ξ > < Ξ

- Most results are known for saturated networks and cannot be reduced to unsaturated networks
- In practice, the processes are not monotonous
- Development of queue-based algorithms which provide maximal stability, but are very difficult to implement and lead to high delays
- Assume *Standard* CSMA:
 - (a) Each node does not know its neighbors
 - (b) Access procedure is the same for all nodes
 - (c) The node does not access the network if its queue length is empty

- A Loose Stability Condition
- 4 Towards a better stability condition

(日) (日) (日) (日)

Line and Circle Topologies

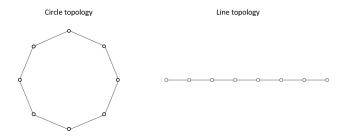

- N transmitter nodes in a circle or a line
- $\mathcal{N}_i(N)$ is the neighborhood of node N:

Circle topology

Line topology

Image: A matrix

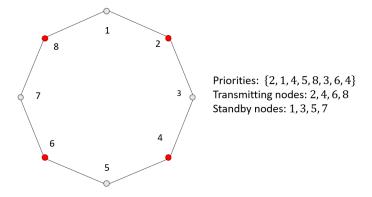

$$\mathcal{N}_{c}(i) = \begin{cases} \{N,2\} \text{ for } i = 1\\ \{N-1,1\} \text{ for } i = N \\ \{i-1,i+1\} \text{ else} \end{cases} \quad \mathcal{N}_{l}(i) = \begin{cases} \{2\} \text{ for } i = 1\\ \{N-1\} \text{ for } i = N\\ \{i-1,i+1\} \text{ else} \end{cases}$$

- All nodes have infinite buffer space. Time is slotted. Transmission time is equal to $1 \end{tabular}$
- $Q_i(n)$: queue size at node *i* at time *n*
- $\xi_i(n)$: number of arrivals at node i at time n. ($\xi_i(n)$ are i.i.d. with $\mathbb{E}[\xi_i(n)] = \lambda$
- Transmission priorities: neighbors cannot all transmit during the same time slot (Medium Access).
 - At each time slot, priorities $\{U_1(n), \ldots, U_N(n)\}$ are allocated
 - The node with priority 1 will transmit if its queue length is not zero
 - Proceed by induction: the next-highest priority node transmits if no node in its neighborhood is transmitting
 - The procedure is repeated until no node can transmit

(日) (同) (日) (日) (日)

Queuing Model

- $D_i(n)$: number of packet transmissions at queue i in time slot n
- Evolution of queue *i* length:

$$Q_{i+1}(n+1) = Q_i(n) - D_i(n) + \xi_i(n)$$

Image: A matrix

1 Model and Notations

2 Parking constants

A Loose Stability Condition

4 Towards a better stability condition

(日) (日) (日) (日)

Parking constant on a line

- Transmission initiation process similar to the discrete-time parking problem

- L_k : expected number of departures in a line ok k non-empty nodes -> expected number of cars parked in a parking lot of k slots.
- $\frac{L_k}{k}$: parking constant (or jamming density)
- Known results: $\left(\frac{L_n}{n}\right)_{n\geq 3}$ is a non-increasing sequence and (see [?]):

$$L_n = \sum_{k=1}^n (-1)^{k+1} \frac{2^{k-1}}{k!} (n-k+1)$$

Lemma

 $L_{k:m}$ expected number of departures from the k first nodes in a network of m non-empty nodes. Then for all $k \le m$:

 $L_{k:m} \leq L_k$

Proof by induction. Write:

$$L_{k:M} = \frac{1}{M} \left(\sum_{i=0}^{k-1} \left(\underbrace{1}_{\text{First node}} + \underbrace{L_{i-2} + L_{k-i-1:M-i-1}}_{\text{First }k-1 \text{ nodes}} \right) + \underbrace{L_{k-1}}_{\text{Node }k-1} + \sum_{i=k+2}^{M} \underbrace{L_{k:i-2}}_{\text{Subsequent nodes}} \right)$$

And:

$$L_{k} = \frac{1}{M} \left(\sum_{i=0}^{k} \left(1 + L_{i-2} + L_{k-i-1} \right) + \sum_{i=k+1}^{M} L_{k} \right)$$

Consequence:

$$L_{k+m} \le L_k + L_m$$

Stability Conditions for a DDMA

< A > < 3

- C_k : expected number of departures in a system of k non-empty nodes in a circle
- Introduce reshuffling (3 versions)
 - Version 1: All queues are reshuffled uniformly at random
 - Version 2: All empty queues stay where they are, all non-empty queues are reshuffled
 - Version 3: All non-empty queues are reshuffled within each non-empty segment

Theorem

For the line topology, the system with reshuffling is stable if $\lambda < \min\{L_N/N, 1/2\}$. For the circle topology, the system is stable if $\lambda < C_N/N$.

- Proof: if $\lambda < \min\{L_N/N, 1/2\}$ for the line topology, or if $\lambda < C_N/N$ for the circle topology, the average number of arrivals in any non-empty segment is lower than the number of departures

(a) < (a)

1 Model and Notations

2 Parking constants

3 A Loose Stability Condition

Towards a better stability condition

Theorem (Foster, 1953)

Let X be a ϕ -irreducible discrete-time Markov chain. X is positive recurrent if and only if there exists a finite set C, a Lyapunov function L and constants $\alpha, \beta > 0$ such that:

 $\Delta V(\zeta) \equiv \mathbb{E}\left[L(X_1) - L(X_0) | X_0 = \zeta\right] \leq \beta \mathbbm{1}\{\zeta \in C\} - \alpha \mathbbm{1}\{\zeta \not \in C\}$

- If the state space is \mathbb{R}^N , it is enough to prove that there exists K > 0 and $\varepsilon > 0$ such that:

$$\Delta V(\zeta) < -\varepsilon$$

whenever $|\zeta| > K$

- Idea: find a suitable function L for the queuing network and deduce a condition on λ for the system to be stable

Theorem

Let ξ be such that $\xi_i(n) \stackrel{L}{\sim} \xi$. If $\lambda < 3/8$ and $\mathbb{E}[\xi^2] < \infty$, the system is stable for both topologies

- For the circle topology. Take:

$$L(x) = \sum_{i=1}^{N} (x_i + x_{i+1})^2$$

- Let $Q(0) = (Q_1(0), \dots, Q_N(0))$ be an initial condition

$$\Delta L(Q) = \sum_{i=1}^{N} \mathbb{E} \left[(Q_i + Q_{i+1} + \xi_i + \xi_{i+1} - D_i - D_{i+1})^2 - (Q_i + Q_{i+1})^2 \right]$$

$$\leq \sum_{i=1}^{N} \left(\mathbb{E} \left[(\xi_i + \xi_{i+1})^2 \right] + \mathbb{E} \left[(D_i + D_{i+1})^2 \right] \right) + 2 \sum_{i=1}^{N} (Q_i + Q_{i+1}) (2\lambda - E[D_i + D_{i+1}])$$

A Loose Stability Condition

- Note that:

$$\sum_{i=1}^{N} \left(\mathbb{E}\left[\left(\xi_i + \xi_{i+1} \right)^2 \right] + \mathbb{E}\left[\left(D_i + D_{i+1} \right)^2 \right] \right) \le 2 \sum_i \mathbb{E}[\xi_i^2] + 2N\lambda^2 + 4N$$

- Bound the second term:

$$\sum_{i=1}^{N} (Q_i + Q_{i+1})(2\lambda - \mathbb{E}[D_i + D_{i+1}]) = \sum_{i=1}^{N} Q_i(4\lambda - \mathbb{E}[D_{i-1}] - 2\mathbb{E}[D_i] - \mathbb{E}[D_{i+1}]])$$

- Make a case study:

 $\begin{array}{l} - \ Q_{i-1} = Q_{i+1} = 0; \ \mathbb{E}[D_{i-1}] + 2\mathbb{E}[D_i] + \mathbb{E}[D_{i+1}] = 2 \\ - \ Q_{i-1} = 1 \ \text{and} \ Q_{i+1} = 0; \ \mathbb{E}[D_{i-1}] + 2\mathbb{E}[D_i] + \mathbb{E}[D_{i+1}] = 1 + \mathbb{E}[D_i] \ge 3/2 \\ - \ Q_{i-1} = Q_{i+1} = 1; \\ \mathbb{E}[D_{i-1} + 2\mathbb{E}[D_i] + \mathbb{E}[D_{i+1}] = (\mathbb{E}[D_{i-1} + \mathbb{E}[D_i]) + (\mathbb{E}[D_i] + \mathbb{E}[D_{i+1}]) \end{array}$

$$\geq 3/4 + 3/4 = 3/2$$

• • • • • • • • • • • •

- We combine the estimates:

$$\begin{split} \Delta L(Q) &\leq \underbrace{\sum_{i} \mathbb{E}[\xi_{i}^{2}] + 2N\lambda^{2} + 4N}_{<\infty} + 2(4\lambda - 3/2) \sum_{i=1}^{N} Q_{i} \\ &\leq C + (8\lambda - 3) \sum_{i=1}^{N} Q_{i} \end{split}$$

- We have $\Delta L(Q) < -\varepsilon$ if $\sum_{i=1}^{N} Q_i \ge K$ with:

$$K = \frac{C + \varepsilon}{3 - 8\lambda}$$
 and $\lambda < \frac{3}{8}$

- For the line topology, we use:

$$\hat{L}(x) = \sum_{i=1}^{N-1} (x_i + x_{i+1})^2$$

- We bound the drift:

$$\Delta \hat{L}(Q) = \sum_{i=2}^{N-1} Q_i (4\lambda - \mathbb{E}[D_{i-1}] - 2\mathbb{E}[D_i] - \mathbb{E}[D_{i+1}]) + Q_1 (2\lambda - \mathbb{E}[D_1] - \mathbb{E}[D_2]) + Q_N (2\lambda - \mathbb{E}[D_{N-1}] - \mathbb{E}[D_N]) = -1$$

- Using the same arguments, the system is stable if $\lambda < \frac{3}{8}$

- Probability of transmission of the node 2/N-1 in the line:
 - N = 4: 3/8
 - N = 5: 11/30
- We can prove that:

 $\lim_{n \to \infty} \mathbb{P}[\text{Transmission of node 2}] = 1 - e^{-1} \approx 0.3679$

- Very well know results in Markov jump processes: the system is stable if $\lambda < \nu$

Is the condition $\lambda < \frac{3}{8}$ tight ?

1 Model and Notations

2 Parking constants

3 A Loose Stability Condition

4 Towards a better stability condition

Fluid limits

- Introduced by Rybko and Stolyar in [?]. Idea: study the average over large jumps in the state space
- Sequence of processes $Q^r(\cdot)$ such that $|Q^r(0)| = r$ is fixed.
- Goal: study the behavior of

$$\bar{q}(t) = \lim_{r \to \infty} \frac{1}{r} \mathbb{E}\left[|Q^r(rt)| \right]$$
(1)

A D A A B A A B A A

Theorem (Dai, 1995, [?])

If the fluid limit model for a fixed queuing discipline is stable, i.e. there exists T > 0 such that $\bar{q}(T) = 0$, then the Markov chain X describing the dynamics of the network is positive Harris recurrent.

- *Remark*: the reciprocal is not true, fluid systems can be unstable and the underlying Markov chain, stable

Fluid limits

- Change the representation of the queueing network:
 - $Q_i^r(t) = Q_i^r(\lfloor t \rfloor)$ is the queue length at node *i*
 - $F_i^r(t) = \sum_{1 \le n \le \lfloor t \rfloor} \xi_i(n)$ is the total number of arrivals at node i up to time t
 - $H_i^r(t)$ is the total numbers of departures from node *i* up to time *t*
- Queue size at node *i* at time *t*:

$$Q_{i}^{r}(t) = Q_{i}^{r}(0) + F_{i}^{r}(t) - H_{i}^{r}(t)$$

- s: occupancy state at node *i* at time *t*, *u*: ranking realization (assignation of priorities)
- $d = \phi(s, u)$: transmission realization.
- Define $\Theta = \{(s, u)\}$ and $\Psi = \{(s, u, d)\}$
- Probability distribution on Θ : $\mathbb{P}_{s}(u, d) = \frac{1}{N!} \mathbb{1}\{d = \phi(s, u)\}$
- $G_B^r(t) = \sum_{1 \le i \le \lfloor t \rfloor} \mathbb{1}\{(s, u, d) \in B\}$: number of time slots during which event $B \in \Psi$ happened

< □ > < □ > < □ > < □ > < □ >

Definition

A fluid limit is a collection of deterministic functions $\chi = [(q_i, f_i, h_i)_{1 \le i \le N}, (g_B)_{B \in \Psi}]$ such that there exists a subsequence r_n such that:

$$\left[\left(\frac{1}{r_n}Q_i^{r_n}(t), \frac{1}{r_n}F_i^{r_n}(t), \frac{1}{r_n}H_i^{r_n}(t)\right)_{1 \le i \le N}, \left(\frac{1}{r_n}G_B^{r_n}(t)\right)_{B \in \Psi}\right] \to \chi \quad \text{u.o.c.}$$

- Temporal evolution of the fluid-scaled system:

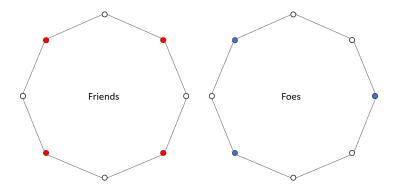

$$\bar{q}_i(t) = q_i(0) + \bar{f}_i(t) - \bar{h}_i(t) = q_i(0) + \lambda t - \bar{g}_{\{d_i=1\}}(t)$$

- Define a probability measure on Ψ :

$$\pi_t(B) = \frac{\mathrm{d}}{\mathrm{d}t} g_B(t)$$

A D > A B > A B

Friends And Foes

- Nodes that are mutual friends have a higher probability of transmission, nodes that are mutual foes have a lower probability of transmission
- Edge nodes have a higher probability of transmission

Image: A math the state of t

- Goal: find $\varepsilon > 0$ such that, for any regular point t such that $\sum_{i=1}^{N} \bar{q}_i(t) > 0$:

$$\sum_{i=1}^{N} \bar{q}'_i(t) \leq -\varepsilon$$

- If for all
$$i > 0$$
, $\bar{q}_i(t) > 0$:

$$\bar{q}_i'(t) = \lambda - \pi_t(\{d_i = 1\}) = \lambda - \frac{C_N}{N}$$

- (C_n/n) is a non-increasing sequence for even values of n, and non-decreasing for odd values of n
- For even values $n \ge 4$, $C_n/n \ge \lim_{n \to \infty} C_n/n = 1/2(1 e^{-2}) > 2/5$ and for odd values $n \ge 5$, $C_n/n > C_5/5 = 2/5$

Stability Condition on a Circle

- If there is at least one i such that $\bar{q}_i(t) = 0$
- Reduce the analysis to *positive groups* of size *l*: groups of nodes such that $\bar{q}_{k+1}, \dots \bar{q}_{k+l}$ such that $\bar{q}_k(t) = \bar{q}_{k+l+1}(t) = 0$ and $\bar{q}_{k+i}(t) > 0$.
- We prove that for any positive group of size l, $\sum_{i=1}^{l} \bar{q}'_{k+i}(t) < -\varepsilon(l) < 0$
- Make a case study depending on the size of *l*:

- If
$$l = 1$$
, we get $\bar{q}'_{k+1}(t) < \lambda + 1/2 + \lambda/4$

- If l = 2, we get $\bar{q}_{k+1}^{\lambda+1}(t) + \bar{q}_{k+2}'(t) < 5\lambda/2 1$
- The same goes for l = 3
- If $l \ge 4$, the worst occupancy state occurs in a segment of length 7 where the middle node transmits, with probability is 179/420 > 2/5

- We thus have:

 $\lambda < 2/5 \implies$ The system is stable

Stability Condition on a Circle

- Remind that $C_N = 1 + L_{N-3}$, and thus, $L_N/N > 2/5$
- If for all i, $q_i(t) > 0$:

$$\sum_{i=1}^{N} \bar{q}'_i(t) = N\lambda - L_N$$

Which is negative if $\lambda < \frac{2}{5}$

- Else: case study as before
- We have to take into account border nodes
- The same result holds:

 $\lambda < 2/5 \implies$ The system is stable

For the circle topology:

- If $\lambda > C_N/N > 2/5$, the system is always instable
- For N = 5, $C_N/N = 2/5$ and the bound is tight, and $\lim_{N\to\infty} C_N/N = 1/2(1-e^{-2}) \approx 0.4323$
- Stability if $\lambda < C_N/N$ is still an open question

For the line topology:

- Some nodes receive a throughput less than 2/5
- Not an intuitive result: need to look at the overall topology and not only node throughput

J. G. Dai.

On positive harris recurrence of multiclass queuing networks: a unified approach via fluid limit methods.

The Annals of Applied Probability, 5(1):49–77, 1995.

A. N. Rybko and A. Stolyar.

Ergodicity of stochatsic processes describing the operation of open queuing networks.

Problems of Information Transmission, 28(3):199–221, 1992.

Seva Shneer and Peter M. van de Ven. Per-site occupancy in the discrete parking problem. *Statistics Probability Letters*, 120:141–146, 2017.
